Observations of high energy trapped electrons and positrons in the inner radiation belt by the PAMELA experiment.

Vladimir Mikhailov (NRNU MEPHI) for PAMELA collaboration

vmikhailov@mephi.ru

- Geomagnetically trapped electrons and positrons with energy above 50 MeV were observed in PAMELA experiment on board Resurs DK satellite. The instrument consists of magnetic spectrometer, imaging electromagnetic calorimeter, time of flight system, anticoincidence and neutron detectors that provide unique particle identification and background rejection. PAMELA was collecting data since June 2006 till January 2016. The satellite orbit with initial altitude 350-600km and inclination 70 degrees crosses the inner radiation belt in South Atlantic Anomaly at L-shell ~1.2. The trapped electrons and positrons were selected on the basis of a trajectory simulation in the Earth magnetic field. Features of energy spectra of electrons and positrons at low energies are analyzed.

**Multi-purpose cosmic ray experiment:**
- Origin, propagation, composition;
- Antimatter component;
- Indirect dark matter detection;
- Solar physics and solar modulation;
- Trapped radiation

**Data analysis**

ToF velocity $\beta$ (left) and topological variable (right) as a function of the rigidity. PAMELA magnetic spectrometer and imaging calorimeter, ToF, AC, provides clean electron identification.

All trajectories of positrons and electrons were tracing back in the Earth’s magnetic field with IGRF field model: altitude $H_{min}=30$ km, $H_{max}=20000$ km, Time of tracing $T_{max}=50$ s. MSIS-90 model for atmospheric density was used for solar quiet condition.

**Orbit**

Satellite Resurs DK was launched 15.06.2006 on elliptical polar orbit with inclination $70^\circ$, altitude 350-610km. Circular orbit with altitude ~570km from September 2010

**Magnetic spectrometer PAMELA**

Geometric factor $\sim 21.6$ cm$^2$sr
Electron/positron energy range 50 MeV - 1 TeV
Energy resolution $\sim 10\%$
Angular resolution $\sim 2$ degrees

**Results:** since July 2006 till January 2016:
- ~3200 days of data taking, ~50 TByte of data downlinked, ~9x10$^9$ triggers recorded

**Detection coordinates of positrons: Albedo, Quasitrapped (left: top, bottom), Galactic and Trapped (right: top, bottom)**

**Differential energy spectrum of electrons ($e^+ + e^-$) for Lshell $\sim 1.2$ B<0.22 (black points) with other measurements and with galactic (Lshell >6, blue) and albedo spectra (B >0.23, Lshell $\sim 1.2$, gray points)**

**Beta vs rigidity distribution for trapped particles. Electron excess is visible at low energies**

**Conclusion**

New particle selection was applied to PAMELA data to obtain clean sample of electrons and positrons from 50 MeV. Energy spectra of the trapped electrons and positrons have similar slope with cut-off at $\sim 2$ GeV. Below 300 MeV excess of electrons over positrons which can not be explained by conventional cosmic ray production mechanism. Possible explanation takes into account e-e scattering mechanism (Phys. Atomic Nuclei v.81.N4, p.520 2018)
